Shades of Grey in Garbage Collection

Mark and Sweep Garbage Collection

Mark: Start from root nodes
and continue to mark the
reachable objects
whatever's left is dead/garbage

Sweep: iterate to all objects in the heap and clean what's garbage

Each object is in one of the three states

live : object is live and is in use

unprocessed: object is not yet processed

processing: object is seen but its children is yet to be processed

We know **Dijkstra** for his 'shortest path' algorithm,

but in 1976/78 he proposed a color abstraction for tracing GC

- * Most modern Garbage collectors are **concurrent** to speed up cleaning, and the **Tricolour Abstraction** comes in super handy to ensure

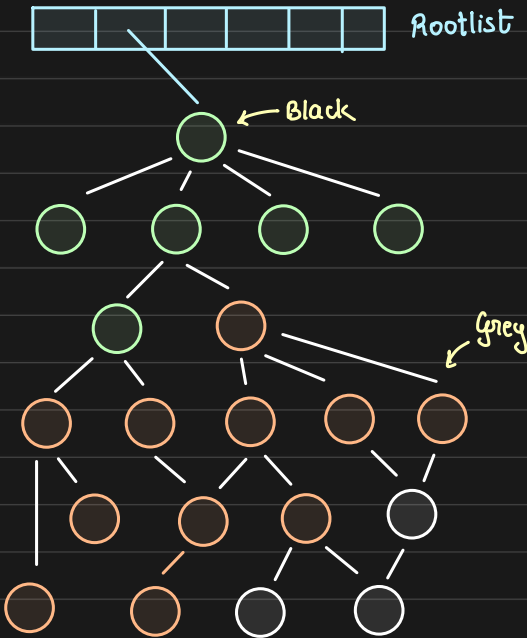

concurrency, smaller pause times, and correctness

Tricolour Abstraction

The object reference graph is partitioned into

BLACK	→ object is LIVE
GREY	→ object is seen but not yet processed completely
WHITE	→ object is not yet seen

Initially every node is **WHITE**, when a node is first encountered during tracing it is coloured **GRAY**, when it has been scanned and its children identified it is coloured **BLACK**

If we visualize tracing based GC we can see it as a wave of Grey nodes moving in the object graph separating the blacks with the whites, untill all nodes turn black

How does tricolour abstraction make thing better?

collector **must** never reclaim the storage of live objects.

WHITE SET : candidate nodes to be garbage collected

BLACK SET : nodes that have no outgoing edge to any WHITE node
nodes that are definitely live so no cleaning them up

GREY SET : nodes reachable from the root but yet to be scanned for its children. nodes are reachable from the root and eventually will be in the black set

What's left in WHITE is garbage collected

Garbage Collection Flow

Pick object from Grey set
and move it to Black set.

Colour each white node referenced
as Grey and repeat the process.

Stack of our DFS

scan is complete when the Grey set is empty

Black objects are reachable from root

White objects are not and hence cleaned up

Because the objects are always moved from White to Grey & Grey to Black
the algorithm preserves an important property

No black object references white

← Ensures that the white
set can be freed once the
grey set is empty.

This is called the Tricolour Invariant

But, why did we do this?

BLACK

GREY

WHITE

Single pass DFS is not fast, but by segregating it across 3 sets, we can reduce the pause time by putting a lot of threads at work on grey set

Hence, the system is halted for a very short time.

Through this, we make our system reactive

↳ instead of periodically running GC, we can monitor the sets and if items > some threshold we can run a quick cleanup

This method is to collect garbage is "on-the-fly" → Dijkstra, Lampart and 3 others

↳ the colour of the nodes are changed by Mutator & not collector and hence the entire GC can be made reactive instead of periodic

and it lays foundation for concurrent GC

where mutator threads runs concurrently with the collector threads.
